Do Banks Still Monitor When There is a Market for Credit Protection?

ABSTRACT

Lenders traditionally rely on specific clauses in loan contracts to commit to monitoring and to protect their interests in credit agreements. The rise of credit default swaps (CDS) provides creditors with an alternative market-based approach to obtaining protection. We find that, once CDS on a given firm begin trading, new loans to that firm have looser creditor protection terms: less collateral and laxer net worth requirements. The effect of CDS on contractual protections is robust to the selection of firms into CDS trading and is stronger when the lenders have easier access to the CDS market. Moreover, loans originated after CDS start trading are less frequently amended. Our findings suggest that financial market development can affect debt contracting by altering creditor monitoring incentives.

Keywords: Credit Default Swaps; CDS; Collateral; Credit Protection; Bank Monitoring

I. Introduction

Banks are special due to their monitoring role in the credit market. To commit monitoring efforts and protect themselves against borrower default, bank lenders often impose requirements on collateral and the borrowing firm's net worth in loan contracts (Rajan and Winton, 1995). Such way of enforcing creditor rights through contracting and the legal system is widespread in credit markets all over the world (Djankov, McLiesh, and Shleifer, 2007). However, monitoring borrowers and ensuring compliance with collateral and net worth requirements are also costly for lenders. When credit default swaps (CDS), a new instrument for credit protection, become available in marketplace, lenders have an alternative means of protecting themselves while avoiding the costs induced by conventional creditor protection.¹ In this paper, we empirically examine whether and how the CDS market affects lenders' commitment to monitoring through the creditor protection terms in corporate loans, such as the collateral requirements and restrictions on firm net worth, as well as through ex post loan contract amendments.

Theoretically, the advent of trading CDS that reference a given firm's debt could lead to either weaker or stronger monitoring by bank lenders. On one hand, with the opportunity to buy protection from CDS market, lenders will no longer fear borrower default and thus demand less protection from loan contract terms such as collateral and covenants.² On the other hand, reducing protection from loan contract terms may induce riskier behavior by borrowers. Such increase in borrower risk can increase CDS prices and reduce the value of protection to lenders. Moreover, anticipating borrower risk-shifting, participant banks of loan syndicates may want stronger commitment from lead banks in order to protect their interests, especially when participating banks and lead banks do not have the same access to CDS market. In such cases, the level of loan contractual protection will either be unchanged or become even tighter.

Given the different ways in which the availability of CDS may affect creditor protection terms in corporate loans, we turn to the data to see which effect dominates.³ We construct

¹Although the most commonly traded CDS contracts reference senior unsecured bonds rather than loans, standard cross-default clauses mean that bonds and loans face default in the same states of the world. Thus, CDS contracts linked to a firm's bonds can hedge the credit risk of its loans, though with some basis risk.

²Reduced use of loan contractual protection terms is viewed as lowered bank monitoring. See Costello and Wittenberg-Moerman (2011) for example.

³Note that in practice, CFOs and loan officers increasingly *do* take the availability of credit protection into account when setting loan contract terms. Habib Motani, a partner at Clifford Chance in London, notes,

a comprehensive dataset covering U.S. corporate loans and CDS trades and run tests for the impact of CDS availability on two common and especially relevant creditor protection terms: collateral requirements and covenants that place minimum requirements on borrower net worth. We find that following the start of CDS trading referencing a given firm’s debt, bank loans to that firm are less likely to be collateralized and have less stringent requirements on firm net worth. This finding is robust to alternative measures of borrower CDS status and to alternative samples.

Although our baseline finding is consistent with the view that the availability of CDS can make lenders tougher bargainers and loosen collateral and covenant requirements, alternative explanations may be at work. For example, CDS trading may be endogenous: lenders that use looser loan contract terms for other reasons may then find it more advantageous to use CDS to hedge their risk, which may encourage an active market for the borrower’s CDS, as predicted by Parlour and Winton (2013). Or there may be selection effects: firms that have CDS contracts written on them may differ fundamentally from non-CDS firms in ways that make a looser loan contract optimal. We mitigate these concerns by examining other restrictions on borrower risk-shifting behavior, and find that our results are not driven by the reverse causality. Besides, we adopt the instrumental variable and propensity score matching approach. Following Saretto and Tookes (2013), we instrument for CDS trading using the amount of foreign exchange (FX) derivatives that the firm’s *past* lead banks and bond underwriters use for hedging (not trading) purposes relative to their total loans.⁴ Our instrumental variable estimation results continue to show a strong negative relation between the onset of CDS trading and loan contractual protection terms. Moreover, we use propensity score matching to construct a matched sample of CDS treated and non-CDS control firms. We then use a difference-in-differences estimator on the matched sample to measure how the actual advent of CDS trading affects loan contracts. We also conduct alternative-sample regressions and within-bank analysis. The result that the advent of CDS trading leads to less collateral and looser net worth requirements remains significant, suggesting that the impact

“when our lending team puts a loan together, they are asked whether it will be deliverable under a credit derivative. If not, then very often it will not be suitable.” He also notes that this situation has only emerged in the last several years. (CFO.com, September 26, 2007)

⁴Lenders active in foreign exchange derivatives hedging are more likely to have expertise that allows them to hedge their loan risk by participating in the CDS market, but *past* lenders’ FX hedging is unlikely to directly drive the choice of contractual protection terms in newly written loans. Our tests show that the instrument is strongly correlated with CDS trading and satisfies the exclusion criterion. This instrument is also used by Subrahmanyam, Tang, and Wang (2014).

of CDS trading on creditor protection terms is causal.

Our analysis implicitly assumes that banks use CDS linked to their borrowers. This assumption is supported by the evidence presented by Acharya and Johnson (2007). Nevertheless, there is substantial heterogeneity in banks' use of CDS. Taking advantage of our unique data on the quantity of CDS trading, we show that the CDS effect is stronger when more outstanding CDS contracts reference the borrower's debt. To the extent that the number of outstanding contracts serves as a measure of CDS market liquidity and, thus, the ease with which lenders can hedge their exposures to the referenced firm, this is consistent with greater availability of CDS contracts enhancing lender bargaining power and reducing loan contracting costs. Moreover, the loosening effect we find should be concentrated on loans for which the lenders actually use CDS. To the extent that a bank with a larger credit derivative portfolio is more likely to have purchased CDS protection on a CDS-referenced borrower, the impact of CDS trading on collateral and net worth requirement should increase with the bank's aggregate credit derivatives position. This is precisely what we find in the data.

Why is the reduced bank monitoring via loosening of loan contractual terms feasible in the case of CDS? An optimal contract design should minimize the opportunity cost of pledging collateral and the expected cost of renegotiating contracts in the future. Loosening creditor protection terms in loan contracts may make it easier for borrowers to engage in risk-shifting and other forms of creditor exploitation. However, for firms where the underlying risk of agency problems is lower, loosening should have little adverse effect compared with the gains of avoiding these costs, whereas the opposite should be true for firms for which this underlying risk is higher. Thus, the degree of loosening should be higher for firms that are less subject to concerns about agency problems.⁵ Accordingly, we run tests in which we interact the availability of CDS on a given firm with proxy for the likelihood that the firm will engage in creditor exploitation. Consistent with theoretical predictions, we find that borrowers with lower credit risk experience *more* loosening in their collateral and net worth requirements following CDS trading, as these firms are less likely to be subject to agency problems.

⁵Gârleanu and Zwiebel (2009) predict that covenants should be tighter when agency problem is more severe. Their theory implies that the impact of CDS trading on loan contractual protection terms should also be smaller for firms with severe risk-shifting incentives. More precisely, if a lender tried to loosen credit terms on a borrower with a higher risk while laying off its exposure by buying a CDS, the CDS seller would be concerned that the borrower would now have few constraints and, thus, would be at high risk of default. To protect itself, the CDS seller would charge a high premium and incur adverse incentives, which would make the CDS transaction less attractive to the lender in the first place.

The analysis regarding firm agency conflict is key to understanding the mechanism behind our story. It suggests that our paper highlights a possible “bright side” to the introduction of CDS contracts. This stands in contrast to much of the empirical literature on credit risk transfer and borrower riskiness has found that the advent of CDS trading for a given firm often causes loan spreads to rise and leads to higher subsequent default rates (see the survey by Augustin, Subrahmanyam, Tang, and Wang (2014) for details). Drucker and Puri (2009) examine the impact of loan sales on initial loan contracting; they find that sold loans tend to be riskier and have tighter and more numerous covenants than loans that are not sold. Our study is also relevant to but different from Wang and Xia (2014), who document that securitization leads to less bank monitoring and riskier borrowers.⁶ In contrast, our findings suggest that CDS-induced contract loosening may not arouse concern as bank monitoring is reduced more for good borrowers.

An implication of the creditor bargaining power theory (e.g., Bolton and Oehmke, 2011) is that loans to CDS-referenced firms should be renegotiated less often. With CDS protection, lenders have little need to compromise during any subsequent debt renegotiations. Knowing this, borrowers will avoid risk-shifting and other behaviors that increase the chance of default in the first place, reducing the possibility that the loan contract be renegotiated in the future. In practice, loan amendments are largely a consequence of the restrictiveness of the initial contracts and a way for borrowers to extract possible surplus that is outside the deal. If lenders reduce monitoring by loosening the initial contract in the first place, then there is less need for future amendments. Examining loan amendment data, we find that this is indeed the case. This finding suggests that the use of CDS protection may help reduce the costs associated with loan renegotiations.

To the best of our knowledge, this is the first empirical paper to study the impact of the credit derivatives market on non-pricing loan contract terms. Extant literature focuses on how CDS affect quantity and price of debt financing. For instance, Saretto and Tookes (2013) find that the advent of CDS trading allowed borrowers to increase their leverage and their debt’s

⁶Wang and Xia’s findings suggest that securitization-active banks monitor their corporate borrowers less intensively than other banks do: loan covenants are looser, borrowers increase risk more after loan origination, and lenders are more likely to waive covenant violations without requiring any change in loan terms. Our paper differs in three key respects: first, and most obviously, we focus on the impact of CDS rather than on loan securitization; second, we are able to focus on the impact of CDS activity tied to a specific borrower; third, we examine how differences across borrowing firms affect the impact of CDS on collateral and net worth requirements. Finally, CDS typically cover higher-quality borrowers, while junk-rated loans are more often securitized. Therefore, our analysis complements Wang and Xia’s analysis.

average maturity. Ashcraft and Santos (2009) study how the advent of CDS trading affected loan spreads.⁷ Focusing on non-pricing terms allows our paper to complement the literature by understanding CDS effects on bank monitoring. This study is closely related to Martin and Roychowdhury (2015), who find a decline in borrowing firms' reporting conservatism after CDS trade initiation. Our findings are consistent with and complementary to theirs in the sense that we provide empirical support for their key assumption on the reduction of monitoring by bank lenders after the onset of CDS trading.⁸ CDS trading can provide information to the market, as shown by Batta, Qiu and Yu (2015), in such case creditor monitoring can be less valuable.

The upshot of our study is that the introduction of CDS contracts has had a significant impact on the design of corporate loan contracts, which is most pronounced for borrowing firms for which the adverse consequences of contract loosening are likely to be smallest. Our findings are most consistent with models that focus on the impact of CDS on lender-borrower bargaining power and the ensuing effects this has on ex ante debt contract design. It is often argued that initial loan collateral and covenants are typically set too tight and are subsequently loosened (e.g., Dichev and Skinner, 2002; Denis and Wang, 2014); thus, our finding that *initial* requirements on collateral and net worth loosen when CDS are introduced suggests that CDS may improve contracting efficiency, especially for high-quality borrowers. Nevertheless, although our results are certainly consistent with the notion that banks are most likely to actually use CDS to hedge their loans precisely in the cases where it improves contracting efficiency and firm value, further work is needed to establish whether and to what extent the effects are welfare improving.

The remainder of our paper is organized as follows. Section II discusses the relevant theoretical literature, its empirical predictions, and our relationship to existing empirical work.

⁷One stream of literature focuses on the risk consequences of the underlying firm. For example, Karolyi (2013) shows that borrowing firms increase their operational risk after CDS begin trading on their debt. Arentsen, Mauer, Rosenlund, Zhang, and Zhao (2015) find similar evidence for mortgages. Subrahmanyam, Tang, and Wang (2014) suggest firms become more default risky after they become CDS referenced. Demiroglu and James (2015) study the role of CDS in debt restructuring.

⁸A body of literature studies the consequences of changes in bank monitoring on corporate behavior. For example, Dhaliwal, Hogan, Trezevant and Wilkins (2011) find that the absence of bank monitoring amplifies the positive relation between weak disclosure and cost of debt. Vashishtha (2014) documents that firms reduce disclosure after delegation of monitoring to banks. Our paper connects to this literature by analyzing one important circumstance in which banks have an incentive to reduce monitoring in the first place. In a contemporaneous study, Chakraborty, Chava, and Ganduri (2015) find that creditors exercise fewer control rights after covenant violations when CDS are available, especially when lenders have less to gain from monitoring the borrowers, such findings are consistent with our idea of less creditor monitoring.

Section III describes our data and empirical specification. Section IV presents our baseline empirical results, addresses endogeneity and selection concerns, and tests more complex predictions of how the effects of CDS trading should vary across firms and lenders. Finally, Section V concludes.

II. Literature, Related Theories and Testable Hypotheses

There is relatively little theoretical work directly modeling how the ability to trade CDS affects the choice of non-price debt terms. We combine theories of how CDS affect borrower-lender interactions with theories of debt contract design to derive a number of predictions that we can test using the data. After establishing these predictions, we show how our analysis relates to existing empirical work on loan contract design and on the impact of CDS trading on bank monitoring.

Prior theoretical work on CDS trading and borrower-lender interactions emphasizes two effects, both of which follow from the fact that a lender that buys CDS protection on its borrower is now insulated from that borrower's risk of default yet retains the control rights embedded in the loan contract. The first effect, emphasized by Morrison (2005), Hu and Black (2008), and Parlour and Winton (2013), is that once the lender has bought protection against borrower default, it no longer has an incentive to engage in costly loan monitoring or, indeed, in any costly ex post actions aimed at improving the borrower's situation. If it is possible to purchase CDS protection for a given borrower anonymously, the borrower will not be monitored at all, nor will the CDS sellers make up for this by monitoring the borrower: they lack the control rights that allow them to act on observations from such monitoring.⁹ If instead, the CDS purchaser's identity is known to its CDS counterparties, banks will make use of CDS only when the benefits of monitoring are negligible to begin with.

The second effect of CDS trading, emphasized by Bolton and Oehmke (2011), Campello and Matta (2013), and Arping (2014), is that lenders with CDS protection no longer have to worry about the borrower defaulting because this triggers payment from CDS sellers, which in

⁹Moreover, Biais, Heider, and Hoerova (2015) argue that bad news about borrowers may lead protection sellers to underinvest in reducing the risk of *their* own assets, generating endogenous counterparty risk for CDS buyers.

turn makes these lenders much tougher bargainers in loan renegotiations aimed at preventing costly bankruptcy or liquidation. This gives the borrower more incentive to avoid anything that will trigger such renegotiations, which should lead to less frequent strategic default aimed at extracting surplus (as in Bolton and Oehmke, 2011) and greater borrower effort to avoid poor outcomes in the first place (as in Arping, 2014). The two effects of CDS trading may have implications for borrower and lender's incentives and lead to changes in debt contracts, which we explain below.

As noted in the previous section, in order to prevent moral hazard and reduce losses in default, lenders often demand that the borrower pledge collateral concerning the borrower's ability to repay the loan. However, using collateral imposes costs on both lenders and borrowers. Collateral is rarely as valuable to the lender as it is to the borrower, and the lender must expend costly effort on making sure the collateral exists and is of sufficient quality and quantity; moreover, as we have noted, pledging collateral now reduces the borrower's ability to pledge it in the future when needs become greater. This means that borrowers and lenders will both have incentives to substitute CDS for collateral *if* CDS are a cheaper means of providing both lender protection and reducing borrower moral hazard. However, if lenders' use of CDS exacerbates borrower agency problems, then CDS sellers will charge higher premiums and lenders may demand the same or even higher collateral requirements as a cheaper means of protection.

Most theories of why lenders require restrictive covenants such as minimum net worth focus on preventing ex post exploitation of the lender by the borrower; examples include Berlin and Mester (1992), Rajan and Winton (1995), and Gârleanu and Zwiebel (2009). Such covenants are also costly.¹⁰ The optimal level of monitoring will depend on the likelihood of exploitative behavior: factors that make exploitation less likely, such as lower default risk, allow the optimal level of monitoring to be lower, and vice versa. These arguments should apply most forcefully to restrictions/requirements that are based on more easily observable accounting information such as net worth because these covenants are likely to be more useful in aligning the interests of equity holders and debt holders (Aghion and Bolton, 1992; Christensen, Nikolaev, and Wittenberg-Moerman, 2016). Moreover, a net worth requirement

¹⁰They may require that the lender monitor at a cost (as in Rajan and Winton (1995) and Guay (2008)); in addition, they may prevent the borrower from pursuing useful projects or be violated in circumstances where default and bankruptcy are inefficient, either of which will require costly renegotiation (as in Berlin and Mester (1992) and Gârleanu and Zwiebel (2009)).

can be viewed as a function of earnings (Core and Schrand, 1999) and specifies the lower bound of firm assets at default, which is exactly the sort of protection a CDS contract offers. Because risk-shifting and other forms of exploitative behavior are more likely to occur when a firm's net worth is low (Gârleanu and Zwiebel, 2009), we expect any CDS effect to be most acute for covenants linked to the borrower's net worth. As in the case of collateral, both borrowers and lenders will have incentives to substitute CDS for tight net worth requirement *if* CDS provide a cheaper way of preventing exploitative behavior by borrowers. The data for calculating the tightness net worth requirement are also relatively clean compared with other types of covenants which may require firms to report financial measures that demand additional auditing and processing (Guay, 2008).¹¹

Matters are somewhat different if, as argued by Rajan and Winton (1995), the failure to monitor impairs lenders' ability to detect covenant violations in the first place. In such a situation, CDS would lead to no effective controls on borrowers, making CDS protection extremely (and perhaps prohibitively) expensive, which should make it less likely for CDS to be available on borrowers whose covenant variables themselves require intensive monitoring. That said, our empirical focus on collateral and net worth, which are easily monitored, should make this issue less critical. The above arguments lead to the following hypothesis for our empirical test:

HYPOTHESIS 1 The onset of CDS trading is associated with a reduction in creditor protection via loan contract terms.

Our implicit assumption is that lenders will purchase CDS if they are available at a reasonable cost. As already mentioned, the cost of CDS protection may become unattractive if CDS sellers expect significant agency problems and subsequent defaults. Lenders may also forgo CDS protection if such contracts are difficult to arrange or if the lender has little understanding of the pricing and operation of such contracts.¹² This suggests that lenders will be more likely to purchase CDS if there is a liquid market for these contracts or if lenders have significant expertise in using credit derivatives. Thus, the impact of CDS on loan contract terms should be more pronounced in these situations.

¹¹Nevertheless, we do examine other types of covenants that limit debt issuance and aim at preventing risk-shifting activities and report the results in the internet appendix.

¹²Minton, Stulz, and Williamson (2009) argue that banks' CDS positions are intended mostly for trading purposes; however, if banks do not link CDS to loans, then we should not find any CDS effect on loan terms.

HYPOTHESIS 2 The reduction in loan contractual protection should be larger for firms (i) that have an active CDS market and (ii) that borrow from CDS-using banks at the onset of CDS trading.

Note that one line of argument or other needn't always dominate. For firms in which borrower agency problems are especially severe, loosening credit terms is likely to be especially costly: such firms will still focus on exploiting their lenders through risk-shifting and similar behavior. In this case, we would expect that CDS will lead to no change in, or even the tightening of, credit terms. By contrast, for firms in which agency problems are less severe, loosening terms while toughening lender bargaining power should be more likely to be beneficial.

Lead banks may be concerned for their reputation as monitors. In order to convince other banks to participate in the loan syndicate, lead banks may increase collateral and net worth requirements so as to commit to monitor. However, if lead banks and participating banks have a prior working relationship and can trust one another, then this commitment effect may be weaker.

HYPOTHESIS 3 The reduction in loan contractual protection following CDS trading should be larger for firms (i) in which risk shifting is not as consequential, or for whom (ii) lead and participating banks have prior collaborations.

Loan contracts are frequently amended after the closing (see, e.g., Roberts and Sufi, 2009). If above hypotheses about CDS effects on *ex ante* incentives of lenders are correct, we expect consistent *ex post* effect from large sample in terms of loan amendments. Therefore, we analyze loan contract changes subsequent to the initial closing.

HYPOTHESIS 4 Loans originated after CDS market inception are less frequently amended.

III. Data and Summary Statistics

We compile data on CDS introduction and loan contracts for U.S. corporations from 1994 to 2009. CDS introduction data are difficult to retrieve from a single data source, given that CDS are not traded in centralized exchanges (the central clearing of CDS began in 2013, which

is after the end of our sample period). Similar to Subrahmanyam, Tang, and Wang (2014), we assemble CDS introduction data from two major transaction data sources: CreditTrade and GFI Group. The CreditTrade data cover the period from June 1997 to March 2006. The GFI data cover the period from January 2002 to April 2009. Both databases contain complete information on intra-day CDS binding quotes and trades. We identify the first trading date for each firm's CDS from these two real transaction data sources. We focus on CDS contracts written on non-sovereign North American corporate issuers. The overlapping period of the two databases from January 2002 to March 2006 allows us to cross-check the first CDS trading dates. We further validate our CDS introduction dates with Markit quote data to ensure accuracy.

To account for the liquidity of CDS transactions and the ease of access to the CDS market for investors, we retrieve data on the quantity of CDS trading and outstanding positions. The detailed transaction data include contract specifics such as size, maturity and credit event clauses. We assemble data on the daily number of CDS contracts outstanding on each firm's debt, and we aggregate the number of outstanding CDS contracts by quarter to be consistent with the frequency of borrowers' financial information.

Our loan contract data are obtained from Loan Pricing Corporation (LPC)'s Dealscan. We combine firm financial data from Compustat with loan data using the link file provided by Chava and Roberts (2008). We obtain loan contractual protection data and other loan characteristics from initial loan contracts covered in Dealscan. The initial sample includes the private debt agreements made by bank and non-bank lenders to U.S. corporations during the period from 1981 to 2009. The Dealscan database contains between 50% and 70% of all commercial loans in the U.S. issued during the early 1990s (Chava and Roberts, 2008). Dealscan coverage increases to include an even greater fraction of commercial loans from 1994 onward. Moreover, the first CDS trading in our sample occurred in 1997. Firm fundamentals may change significantly from the early observations before CDS introduction to after CDS introduction if the time span is too large. We therefore start our loan sample period in 1994. The loans in Dealscan are reported at the facility level. We aggregate facilities in the same loan packages (deals) to conduct our analysis at the loan package level because the net worth requirement is specified at this level. Loan security information is reported at facility level; however, facilities that belong to the same package usually have the same security status.¹³

¹³Out of the raw sample of 32,022 loans with security information available, only 508 loans contain both

Other loan characteristics, such as the dollar amount, maturity, loan spread, loan type and loan purpose are reported at the facility level. We define the loan amount as the total amount aggregated across facilities that compose a loan package. Loan maturity and loan spread are the simple average maturity and average all-in-drawn spread of all facilities in the same loan package.

We obtain our data on collateral and net worth covenants from Dealscan. In Dealscan, whether a loan is collateralized is denoted by the indicator “secured”. If “secured” takes the value of “Yes”, the repayment of the loan is backed by collateral.¹⁴ As is well known, this value is often missing, so we focus on the sample loans that are not missing security status information. We measure the restrictiveness of the net worth requirement by calculating the tightness measure of the net worth covenants introduced by Murfin (2012).

The final CDS introduction sample for our empirical analysis contains 921 unique U.S. firms with CDS trading during the period from June 1997 to April 2009.¹⁵ We start our loan issuance sample in 1994 so that borrowing firms have a pre-CDS control sample period. Table I presents the year-by-year summary of the loans in our sample. The whole sample includes 32,022 loans issued to 9,561 unique firms. Approximately 59.4% loans are secured by collateral. The average net worth requirement is 0.322 for those firms with such covenants, suggesting that the probability of the net worth covenant violation over the next year is 32.2%.

Table I also summarizes the characteristics of loans issued to CDS firms. A total of 2,580 (8.1%) loans are issued to 692 (7.2%) firms that have an active CDS market referencing their debt at loan origination. The number of unique CDS firms peaked at 324 in 2005. The number dropped to 130 in 2008 during the 2007-2009 credit crisis. 39.4% of the CDS-referenced loans are secured, which is approximately half of the level of non-CDS firms’ loans. The average net worth requirement is 0.214 for CDS firms, lower than the average of 0.322 for the whole sample. This suggests that CDS firms are subject to looser the net worth requirement specified in the initial loan contract than non-CDS firms. Table II reports the summary statistics of the loan contractual protection items and other loan contract terms, as well as borrower characteristics. The average loan amount, all-in-drawn spread and maturity for our sample loans are \$320.8 million, 233 basis points and 46 months, respectively. Approximately 33%

secured and unsecured facilities. The other 31,514 loans are either entirely secured or unsecured.

¹⁴A large literature, for example, Murfin (2012), Demiroglu and James (2015), Costello and Wittenberg-Moerman (2011), among others, defines this “secured” indicator using the Dealscan security information.

¹⁵Li and Tang (2016) document that approximately 8% of U.S. firms have CDS referencing their debt.

of the loan borrowers have S&P credit ratings.

IV. Empirical Findings

In this section, we first present our baseline results on the relationship between CDS trading and the level of bank monitoring as proxied for by imposing protection terms in the initial contract. Then, we account for the selection of CDS trading. Furthermore, we provide evidence that the CDS effect on loan contractual protection terms is channeled through CDS transactions. Last, we analyze the mechanisms for the CDS effects.

A. CDS Trading and Debt Contracting: Baseline Results

We conduct a difference-in-differences analysis in our main empirical specifications. The dependent variables for our panel regressions using loan-initiation observations are measures of loan contractual protection terms: whether the loan is collateralized and the strictness of the covenant on net worth. Our key independent variable is *CDS Trading*, an indicator representing whether the borrower’s debt has active CDS trading in the quarter of loan origination. To insulate the CDS effects from factors that drive any systemic differences between CDS and non-CDS firms, we include *CDS Traded*, a dummy representing whether the issuer has a CDS market on its debt at *any* time during the entire sample period. We aim to identify time-series changes in the use of loan contractual protection devices after CDS introduction. Therefore, *CDS Trading* is the variable of primary interest. *CDS Traded* is designed to capture unobservable factors that may drive the different levels of protection in the loan contracts of CDS and non-CDS firms. By incorporating both *CDS Trading* and *CDS Traded* into the specifications, we can identify the effect of CDS trading after the inception of CDS from before CDS introduction for the *same* CDS firm. Moreover, this difference-in-differences setting also helps insulate the CDS effect from any potential time trend in loan contract variables. Specifically, we employ the following specification:

$$\begin{aligned} \text{Loan Contractual Protection}_{ijt} = & \alpha_1 + \beta_1 \text{CDS Trading}_{ijt} + \beta_2 \text{CDS Traded}_i \quad (1) \\ & + \gamma_1 \text{Controls}_{ijt} + \gamma_2 X_{1i} + \gamma_3 X_{2t} + \epsilon_{ijt} \end{aligned}$$

where i represents the borrowing firm, j represents the loan, and t represents the loan origination time. We include a host of control variables identified in prior studies as determinants of loan contract terms to ensure that the effect comes from CDS trading and that it is not driven by other loan or borrower characteristics. Specifically, the loan-level control variables include the loan issuance amount, maturity, loan spread and the number of lenders in the loan syndicate.¹⁶ We aim to mitigate effects from credit risk using borrower-level characteristic variables; therefore, we include the logarithm of total assets, a dummy representing whether the firm has an S&P rating, and Altman’s Z-score in the specifications. Controls of borrower characteristics are extracted at the end of the quarter prior to loan initiation. In addition to including the loan origination year and borrower industry fixed effects, we construct dummy variables for loan purposes to account for any possibility that the level of loan contractual protection systematically varies across loans issued for different purposes.¹⁷

Table III presents the baseline OLS regression results under the difference-in-differences framework. The dependent variable for models 1 and 2 is a dummy representing whether the loan is secured by collateral. *CDS Trading* and *CDS Traded* are positively correlated because only CDS firms can have active CDS trading at loan origination. We show the estimation results of *CDS Trading* both with and without the inclusion of *CDS Traded* to demonstrate that the CDS trading effect is distinct from the CDS firm effect. Controlling for the loan origination year, borrower industry and loan purpose effects, column 1 shows that the marginal effect of CDS trading on the probability that the loan is secured by collateral is -0.076 (or 21.1% relative to the proportion of secured loans for the CDS firms three years prior to CDS introduction). The coefficient estimate is -0.113 when the CDS firm effect is not accounted for. These coefficient estimates are statistically significant and at a plausible economic magnitude. We cluster standard errors by firm to eliminate the cross-dependence of contractual characteristics within firms.

Similar CDS effects are obtained with the net worth requirement measure in models 3 and 4, where the dependent variable, net worth requirement, is measured by the strictness of net

¹⁶We include both syndicated loans and sole-lender loans in our sample. For sole-lender loans, the number of lenders is set to one.

¹⁷Major loan purposes specified in the contracts include general corporate purposes, working capital, debt repayment, takeover, and CP backup.

worth covenants (Murfin, 2012):

$$\text{Net Worth Requirement} = 1 - \Phi\left(\frac{w - \underline{w}}{\sigma}\right), \quad (2)$$

where w is the logarithm of current net worth of the firm at loan initiation. \underline{w} is the logarithm of the minimum net worth that the firm is required to maintain before the loan is matured. The coefficients of *CDS Trading* are negative, suggesting that the minimum requirement for the firm’s net worth is loosened after CDS trading is introduced. The estimation results on other explanatory variables are consistent with the literature. For example, borrowers that are larger, have an S&P rating or have a higher Z-score have imposed relatively looser net worth requirements. Such borrowers are less likely to be financially constrained, and so less subject to borrower-lender agency problems.

These findings suggest that lenders exert less monitoring efforts via loan contractual protection terms when they can obtain protection from the CDS market. Lenders become less concerned about their claims on collateral and about shareholders’ “skin in the game” when they can separate cash flow rights through the CDS market. This is a result of the possibility that the direct and indirect costs of monitoring loan contractual terms may outweigh the cost of using CDS for hedging.¹⁸

In terms of CDS effects on the pricing terms of loans, Ashcraft and Santos (2009) find that loan spreads increase after the onset of the reference firm’s CDS trading. Hence, the lender may be compensated with higher rates for reduced contractual protection.¹⁹ Table III shows a reduction in loan contractual protection even when loan spread is controlled for. Although CDS may not directly benefit borrowers in terms of the lowered cost of debt, borrowers may indirectly benefit through less restrictive non-pricing terms and lower contracting costs.

B. Addressing the Selection of CDS Trading

Our study, similar to others on the impact of CDS trading, is subject to the concern that CDS firms are not randomly assigned and that the starting point of CDS trading can be

¹⁸Sustersic (2012) uses a smaller sample and finds that financial covenants become stricter after CDS trading. We have also analyzed financial covenants but found an insignificant effect, especially after accounting for the selection of CDS trading.

¹⁹This is similar in spirit of Beatty, Ramesh and Weber (2002), who find that borrowers pay substantially higher interest rates to retain accounting flexibility that may help them avoid covenant violations and to avoid duplicate record-keeping costs.

endogenously determined. This endogeneity has two possible sources. The first is reverse causality: lenders may have a greater demand for hedging contracts such as CDS when they anticipate a greater supply of unsecured loans or loans with less-restrictive contracts. We conducted a supplementary analysis, constraining the sample by skipping observations in which loan contracting is within one year, two years or three years after first CDS trading, and found similar results (see Table IA1 of the Internet Appendix), suggesting that our findings are not due to reverse causality. Our reasoning is that it may be possible for lenders to anticipate changes in loan contracts in the near future, but it becomes more difficult to expect changes in the remote future, such as in three years. Thus, the reverse causality problem is more likely to occur for the observations right after CDS introduction and become less severe as time passes.

The other source of endogeneity is the omitted variable problem. Specifically, CDS firms are not randomly assigned in the sense that some factors that drive the contract to be looser may also determine the likelihood of the firm to be selected into CDS referencing. For instance, changes in borrowers' riskiness over time may explain contract features as well as the onset of CDS trading. However, Subrahmanyam, Tang and Wang (2014) show that firms become more default prone after they are referenced with CDS. Higher default risks should lead to more collateral protection and drive net worth requirements to become tighter rather than looser. Therefore, predictions from the omitted correlated variables oppose our findings.

Nevertheless, we formally address the endogeneity issue using various econometric techniques. The selection of firms into CDS trading will result in biased coefficient estimates on *CDS Trading*, which may be correlated with the regression error term. Specifically, we are interested in obtaining

$$\text{Treatment Effects(TT)} = E(Y_1|X, D = 1) - E(Y_1|X, D = 0) \quad (3)$$

while we are only able to observe

$$\text{Treatment Effects(TT')} = E(Y_1|X, D = 1) - E(Y_0|X, D = 0) \quad (4)$$

where D indicates whether the observation receives treatment. We want to observe how treatment firms would have behaved if they were not treated. To make TT' as close to TT as possible, we employ the instrumental variable (IV) approach by carrying out a two-stage-least-squares (2SLS) regression. Second, we use the propensity score matching approach by

assuming that all factors that determine CDS introduction are accessible. These approaches are standard and can potentially alleviate the endogeneity concern.

B.1. Instrumental Variable (IV) Approach

The endogeneity concern we have is about the correlation between our main variable of interest, *CDS Trading*, and the residual term in the loan contractual protection regression. We use instrumental variables for *CDS Trading* to address this correlation issue. The ideal instrument should affect loan contract terms only through *CDS Trading*. Our instrument, *Past Lender’s Foreign Exchange Derivatives*, is selected based on the existing literature, namely, Saretto and Tookes (2013) and Subrahmanyam, Tang and Wang (2014). This instrument is the amount of foreign exchange derivatives used for hedging (not trading) purposes relative to the total loans of the lead syndicate banks a firm has borrowed from during the past five years. This variable is constructed for each firm as the average across all banks that have served as a syndicate member over the past five years. The ratio is lagged by one quarter when included in the first-stage regression. Lenders’ foreign exchange derivative data are available from the Federal Reserve’s Call Report, which tracks the lending banks’ quarterly derivatives usage and the compositions of their loan portfolios. The idea is that banks that hedge their loan portfolios are generally more likely to be active risk managers and use more than one type of derivative. Thus, this instrumental variable captures the hedging demand of firms’ creditors and is expected to be related to the existence of CDS markets for firms’ debt.

We believe that this instrumental variable broadly satisfies the two conditions for valid instruments. First, the partial correlation between the instrument and the endogenous variable is not zero. The relevance condition requires that the coefficient γ in the regression

$$\text{Prob}(\text{CDS Trading}_{it}) = \alpha + \beta \text{Past Lender’s Foreign Exchange Derivatives}_{it-1} + \gamma \text{Other Borrower Characteristics}_{it-1} + u_{it} \quad (5)$$

does not equal zero, where x_{it-1} refers to a set of borrower characteristic variables that explain the onset of CDS trading. The *relevance* requirement essentially translates to the first-stage regression. We employ the OLS regression of *CDS Trading* on the t-1 (one-quarter-lagged) value of the *past* lender’s foreign exchange derivatives, controlling for other firm characteristic variables. Consistent with our expectation, a larger *past* lender’s foreign exchange derivatives

hedging position relates to a higher probability of CDS trading, i.e., the probability of a firm being selected into CDS trading. The partial correlation between the instrumental variable and *CDS Trading* is both economically and statistically significant. Borrower characteristic variables, x_{it-1} , include a set of factors that may determine the potential hedging demand of investors. Some of these variables proxy for firm financial constraints, including firm size, leverage, current ratio, profitability, cash-to-assets ratio and fixed charge coverage. We also include variables that measure firm credit risk, such as Altman’s Z-score. We also consider redeployability of firm assets (tangibility, the ratio of tangible assets to total assets) and market-based measure of financial performance (excess stock return), risks (stock return volatility) and valuation (market-to-book). The first-stage regression results are reported in Internet Appendix Table IA2. Overall, coefficients of the explanatory variables suggest that larger firms, firms that are more financially constrained, and firms with higher credit risk and lower market valuation are more likely to be referenced with CDS.

The second requirement for a valid IV is the *exclusion* condition $cov(IV, \epsilon)=0$. That is, the instrument influences the outcome *Loan Contractual Protection* only through its effect on the endogenous variable *CDS Trading*. A lender’s foreign exchange derivatives position is a macro hedge and characterizes the lender’s global risk management strategy. More importantly, the firms in our sample are U.S. firms, making a bank’s decision to hedge foreign exchange exogenous to its domestic borrowers’ U.S. dollar-denominated loan contracts. Finally, the instrument is constructed based on the lender’s *past* derivative position, which should not affect the firm’s *current* lender monitoring level. Therefore, this variable is unlikely to directly affect loan contractual protection measures.

The second-stage estimation results using the fitted values of *CDS Trading* are reported in Table IV. The coefficient estimates on the instrumented *CDS Trading* are negative and statistically significant at 5% or better. This evidence is consistent with a causal interpretation of the CDS effect on loan contractual protection. Recognizing the limitations of the IV approach, we next use alternative approaches to further tackle the endogeneity concern.

B.2. Propensity Score Matching

Our ultimate goal is to purge the marginal effects of CDS trading on loan contractual protection. However, it is impossible to obtain a treatment group to observe what firms would have

experienced had they not experienced the treatment because firms are not randomly assigned to be treated with or without CDS trading. The approach of propensity score matching is aimed to address the selection bias issue. We attempt to observe whether the changes in loan contract items are still robust after pairing each treatment firm (CDS firm) with a matching firm (non-CDS firm) whose propensity to have CDS trading is nearest that of the treatment firm. We need to ensure that any change in loan contractual items is due purely to the advent of CDS trading instead of other factors that determine the firm’s “selection” into the treatment group.

First, we use a probit regression to estimate the propensity score, which measures the possibility that a borrower’s debt is referenced with CDS trading. The sample we use for the first-stage regression includes all loan quarters for non-CDS firms and only the loan quarter observations from the year 1994 until the first quarter that CDS trading begins for CDS firms. Given the trade-off between full information and possible selection bias due to incomplete Compustat information, we incorporate all relevant variables that may potentially affect CDS introduction conditioned on data availability. The explanatory variables for estimating the propensity score include the one-quarter lag of the following: the *past* lender’s foreign exchange derivatives position (for hedging), logarithm of total assets, current ratio, return-on-assets, leverage ratio and Altman’s Z-score.

Next, we pair CDS firms with a control group using *Nearest Neighborhood Matching*. Among the 692 CDS-referenced firms with collateral information available, 658 firms are paired with one matching firm each. Internet Appendix Table IA3 reports the comparison of loan characteristics for CDS and non-CDS firms before and after matching. Loans from the matched firms have much more similar characteristics to loans from CDS firms. The difference in the propensity score between firms with and without CDS trading decreases from 0.211 before matching to -0.007 after matching. More importantly, the propensity score difference becomes statistically insignificant after matching. Table V reports the regression results using the matched sample constructed from the prediction model. The coefficient estimates for *CDS Trading* remain significantly negative, suggesting that the observed CDS effect on loan security is not driven by characteristics that select the firm into the treatment group.

B.3. Other Analyses to Address Endogeneity Concerns

To further eliminate the reverse causality concern that firms that have a looser loan contract happen to become CDS-referenced for some other reasons, we examine other types of financial covenants that restrict borrower risk-shifting behavior. The most relevant covenants are those restricting debt ratios, including debt-to-EBITDA ratio, debt-to-tangible net worth ratio and leverage ratio. Our choice of covenants also concerns clearness of data and prevalence across sample firms. We conduct the same analyses for these debt restrictions and report the results in Table IA4. As shown by the coefficients of *CDS Trading*, the tightness of these debt-ratio covenants is not significantly associated with the availability of CDS trading. This suggests the relation between CDS trading and covenant tightness is not a mechanical relation across all types of restrictions, and that it is not driven by certain borrower traits that enable the firm to obtain generally looser loan terms and also determine the start of CDS trading. Instead, the effect is only relevant to the restriction on net worth, which ensures repayment ability most forcefully.

Another endogeneity concern is that the lowered contractual protection may be due to different lending strategies employed by different banks. One possibility is that banks that lend to CDS firms are totally different from banks that lend to non-CDS firms and that the former always write looser contracts. Such a predetermined bank-borrower match may contaminate our findings. To address this concern, we restrict the sample of lending banks to those that lend to both CDS and non-CDS firms. Furthermore, we restrict the sample to banks that lend to CDS firms both before and after CDS trading. Panels A and B of Internet Appendix Table IA5 show the results of the “within-bank” analysis and demonstrate that our findings are robust to the possible selection of banks. Heterogeneity in banks’ lending strategies does not seem to be the driving force for the changes in loan contractual protection devices.

C. Quantitative Effects of CDS

Thus far, we have shown that bank monitoring via loan contract terms is less intense for new loans issued after the advent of CDS. Our analysis implicitly assumes that lenders actually purchase the CDS of their borrowers. Acharya and Johnson (2007) provide evidence supporting this assumption (see Augustin, Subrahmanyam, Tang, and Wang (2014) for more detailed

discussion). In this section, we demonstrate that the CDS effect on bank monitoring is more pronounced when the CDS market is more liquid and when lenders are indeed active CDS users.

C.1. CDS Market Liquidity

If CDS provide alternative protection for lenders and loosen credit terms, then the magnitude of the effects should depend on the costs of buying CDS. If the underlying credit is too risky or the CDS transaction is difficult to arrange, then the cost of buying CDS protection would be unattractive and the effect of CDS limited. In this case, we should expect CDS effects to be stronger when the cost of using CDS is lower. This could be the case when the CDS market referencing the borrower’s debt is more liquid, as lenders would find a greater ease of access to the CDS market and more likely trade CDS at fair prices.

We construct measures of CDS market liquidity to test this prediction. CDS liquidity is difficult to measure because CDS contracts are not exchange traded and not continuously traded. Our transaction data record each trade for a given index firm and for specific contract terms, such as expiration dates. Therefore, we can calculate outstanding CDS positions by summing all contracts that have not yet matured in a given quarter. The positions are in dollar terms. We further scale this dollar amount by the total value of debt outstanding of the reference firm to make the ratio more comparable across large and small firms. This relative CDS amount outstanding can be understood as the “open interest” of CDS, and it is our first liquidity measure. We also calculate for each reference issuer the trading volume in a given time period, such as a quarter, by counting the total number of transactions, which is our second CDS liquidity measure.²⁰

We extend the baseline analysis by replacing the CDS trading indicator with these two CDS market liquidity measures. The regression estimation results are reported in Table VI. Model 1 shows a significant and negative coefficient estimate for *CDS Outstanding Amount/Total Amount of Debt* while controlling for CDS firm characteristics and other loan and firm characteristics. We find similar results in model 3 where we use net worth requirements as the

²⁰Alternatively, we construct the two measures on a monthly basis and report the regression results of the monthly variables in Table IA6. The loan syndication process usually takes between one and three months. Ivashina and Sun (2011) document that the number of days between the formal start of syndication and the loan closing day is, on average, approximately four weeks. Before the launch, the lead bank discusses the deal structure with the issuer and obtains credit ratings.

dependent variable. Because it is likely that part of the outstanding CDS positions is held by existing lenders (see Acharya and Johnson, 2007). This measure should be positively correlated with the lender’s hedged positions. When much of the firm’s debt is already hedged with CDS, creditors will be better able to initiate a new loan. Hence, they can offer a looser loan contract that is more favorable to the borrower. We find similar results when we use the scaled CDS trading volume as the liquidity measure in models 2 and 4 in Table VI. This suggests that lenders reduce monitoring to a greater extent when the reference firm’s CDS are more actively traded at loan origination.

C.2. Lenders’ Use of Credit Derivatives

Thus far, we have assumed that the lenders do indeed use CDS that reference the borrower’s debt. If we could observe each lender’s CDS portfolio holdings to identify whether and when the lenders use CDS referencing the specific borrower, then we could directly test whether the CDS effects exist only for lenders using the borrower’s CDS. Unfortunately, we do not have such detailed information on lenders’ CDS portfolios. During our sample period, regulations require the disclosure of the lenders’ aggregate credit derivatives position only (more recently, the positions have been separated into hedging and trading positions). Therefore, we use such aggregate data to test whether CDS effects on loan contractual protection are stronger when lenders have larger credit derivatives positions.

We obtain data on lenders’ credit derivatives from the Federal Reserve’s FR Y-9C quarterly report on bank credit derivatives positions for commercial banks and bank holding companies. We interact the lenders’ credit derivatives positions in the quarter of loan initiation with the CDS trading dummy.

$$\begin{aligned} \text{Loan Contractual Protection}_{ijt} = & \alpha + \beta_1 \text{CDS Trading}_{ijt} \times \text{Lenders' Credit} \\ & \text{Derivatives Position}_{ijt} + \beta_2 \text{CDS Trading}_{ijt} \\ & + \beta_3 \text{CDS Traded}_i + \gamma_1 \text{Controls}_{ijt} \\ & + \gamma_2 X_{1i} + \gamma_3 X_{2t} + \epsilon_{ijt} \end{aligned} \quad (6)$$

where *Lenders’ Credit Derivatives Position* refers to the *lead* bank’s credit derivatives position in the quarter of loan initiation. We also use an alternative measure in Table IA7, *All Lenders’ Credit Derivatives Position*, which aggregates *all* syndicate lenders’ positions in the quarter

of loan initiation.

Table VII reports regression results with a focus on the interaction term between borrower CDS availability and lender credit derivatives position. The first two columns report the regression results for collateral, and columns 3 and 4 report the results for the net worth requirement. The coefficient estimates on the interaction terms are negative and statistically significant in all specifications. Moreover, the standalone effect of *CDS Trading* remains negative and significant. Hence, lender CDS usage enhances the effect of CDS trading on the usefulness of loan contractual protection devices. Lender monitoring declines further as the credit derivatives position the lender takes increases.

D. Understanding Lenders' Monitoring Incentives

In this section, we examine the specific situations under which CDS effects are most pronounced so as to understand the mechanisms underlying the CDS effect.²¹ If using CDS reduces bank monitoring via contractual protection in loans, the CDS effect should differ across firms based on the likelihood that less collateral and looser covenants cause an increase in borrowers' exploitative behavior. This likelihood should depend on the severity of borrower-lender conflicts and within-syndicate conflicts among lead lender and participating banks.

D.1. Potential for Borrower Risk-Shifting

For firms for which agency problems are less likely, the decrease in bank monitoring level should have lower costs compared with the gains of avoiding bargaining and renegotiation costs associated with a tighter contract; the opposite should be true for firms for which agency problems are more likely. The potential for borrower-lender conflicts varies across firms: it should be more prominent for firms close to financial distress but more remote for profitable and high-credit-quality firms. Because the possible adverse effect of loosening the initial loan contract should be less severe for firms with better credit quality, the loosening effect from CDS trading should be more prominent for such firms.

We distinguish firms with larger Z-scores using the 50% breakpoints of all sample firms

²¹Our exploration is guided partly by theoretical predictions from Gârleanu and Zwiebel (2009) in terms of potential transfer from debt to equity, conflicts between syndicate lenders, and renegotiation incentive.

in the same quarter. We report the estimation results in Table VIII, with a key interest in the interaction term between the CDS trading indicator and the agency severity dummy. As expected, firms that are more distant from default see a greater reduction in collateral and relaxation of the net worth requirement following the advent of CDS. The coefficient estimates on the interaction terms are both statistically significant and economically meaningful. The results are robust to the inclusion of the CDS firm effect.

Our findings support the prediction of Bolton and Oehmke (2011) that “the commitment benefits of CDS are largest for firms whose creditors’ bargaining position is weak in the absence of CDS.” Shareholders from financially healthier firms have an advantageous position when bargaining against creditors. Both the theoretical models and the empirical evidence show that loans to borrowers with *higher* credit quality are more likely to be hedged using CDS.²² Transferring risks through the CDS market may prove too costly for borrowers facing high agency conflicts. If the CDS seller charges a high premium, it will make the purchase of CDS for protection less attractive to the lender in the first place. Indeed, the results are consistent with our expectations.

D.2. Within-Syndicate Conflicts

The effect of CDS on creditor protection should not only vary with borrower credit quality, but with possible conflicts among lenders within a syndicate. As the lead bank is managing the syndication process and structuring the loan, it has to set reasonable loan contract terms to maximize the chance of a successful syndication (Esty, 2001). Lead banks consider both the borrower’s potential to repay the loan and participant banks’ demand for credit protection when setting the loan contract. In contrast to cases where the lenders have multiple collaborations in the past and are familiar with each other, lead lender monitoring is more important when the lead bank distributes the loan to other participating banks they have never worked with. Put differently, participant banks should be more likely to accept a looser contract if they trust the lead bank more.

We expect that participant banks tend to trust lead banks that they worked with in the same loan syndicate before. We use a dummy *Lead Lender-Participant Lender Past Collaboration* to measure whether any of the participant banks worked with the lead lender

²²In contrast, poor-quality loans are more involved in a secondary loan sales market. See Parlour and Winton (2013), Minton, Stulz and Williamson (2009), and Ashcraft and Santos (2009) for examples.

in the past five years. If CDS reduce lead lender monitoring, such effect should be stronger for loans in which the syndicate lenders have more collaboration in the past. Although it is possible for both lead banks and participant banks to access CDS market, the reality is lead banks use relatively more CDS as they are larger and more matured derivative users. If only the lead lender uses CDS while other participant banks do not, participant banks would still concern and demand sufficient monitoring. However, if the participant banks collaborated with the lead lender before in other deals, they may become less concerned with the repayment risk and accept a less stringent contract.

Table IX shows that the decrease of loan security after CDS trading is more pronounced when the lead bank has collaborated with participating banks in other loan deals in the past. On average, CDS reduce the proportion of secured loans by 1.2% and the tightness of net worth requirement by 2.8%. If the lead bank worked with the participant banks in past syndicate loan deals, the proportion of secured loans is further reduced by 8.9%. Similar results are found for the net worth requirement. These results suggest that when the lead bank and participating lenders have collaboration before, bank monitoring becomes even less important when CDS trading is in place. More collaboration indicates less severe agency conflicts between lenders. Therefore, this finding is consistent with our previous results that CDS mitigate loan contracting costs more when the agency problem of a syndicate is less severe.

E. Are Loans Amended Less Often When CDS are Available?

Thus far, we have shown that CDS provide alternative protection for lenders' cash flow rights and let lenders monitor less via loan contractual devices. As a result, CDS-referenced borrowers receive loan contracts with looser collateral and net worth requirements. These changes should also affect incentives to renegotiate the contract during the life of a loan. Roberts and Sufi (2009b) show that the motivations for amending loan contracts are largely a consequence of the restrictiveness of the initial contracts and improvement in credit quality, as increases in collateral can shift the relative bargaining power in favor of the borrower and make borrowers able to renegotiate more advantageous terms. Denis and Wang (2014) also document that stricter loan covenants are associated with a higher likelihood of renegotiations during the life of the loan. In other words, most renegotiations of loan contracts come from borrowers'

intention to argue for better terms. Given that CDS loosen loan restrictions, borrower may have less incentive to initiate renegotiations. On the lender side, regardless of changes in the initial loan contract items, lenders may also become less interested in renegotiating the loan contract with their borrowers because their payoff is hedged in liquidation, as predicted by Bolton and Oehmke (2011).

We directly examine how the frequency of loan amendments is affected by CDS trading. We obtain the loan amendment information from the “Amendment” table in Dealscan. The “Comments” column lists the amended items in detail. Lenders and borrowers may make amendments to the loan amount, maturity, spread, payment schedule, pricing grid or covenants.

For our sample loans, 14.6% of the loan packages are amended at least once. We acknowledge that this could be a sub-sample of the whole population of loan amendments, as Roberts and Sufi (2009b) report that 64.5% of the 1,000 sample loans that are randomly selected from the SEC filings are ever renegotiated. However, our sample appears to represent the larger loan amendment sample well. In particular, Roberts and Sufi (2009b) document that approximately 28% of loans are renegotiated when time has elapsed by 25%-50% of the stated maturity. This proportion is 30.25% in our sample. The distribution of frequency in other time elapses is also comparable. Ivashina and Sun (2011) report that the average amendment takes place within 18 months of loan origination. We find the average amendment occurs at 16.53 months after loan origination in our sample.

We examine changes in loan amendment possibility and frequency by regressing a loan amendment indicator and the number of amendments on CDS market characteristic variables, controlling for firm characteristics in the quarter before loan amendment. Following the empirical design in Roberts and Sufi (2009b) and Denis and Wang (2014), we control for changes in firm characteristics from loan origination to loan amendment, including changes in profitability (Δ EBITDA/Assets), leverage (Δ Total Debt/Assets), firm size (Δ Log (Assets)) and earnings volatility (Δ EBITDA Volatility). We control for year fixed effects to account for possible changes in macroeconomic conditions over time.

Table X reports the regression results of the frequency of loan amendments on the onset of CDS trading. The coefficients of *CDS Trading* are significantly negative, suggesting that CDS-referenced loans are amended less frequently. Column 1 shows that on average, loans

are 5.5% less likely to be amended after the borrower becomes CDS referenced. Compared with the percentage of amended loans in the whole sample, 14.6%, this is a 37.7% reduction in relative terms. Most of the loans are amended more than once.²³ For the whole sample, each loan receives 0.679 amendments before maturity. Column 2 shows that the average number of loan amendments is reduced by 0.248 (or 36.5% relative to the mean number of amendments) after CDS introduction.

We control for the stated maturity in the original loan contract because longer maturity is related to a higher likelihood that the loan contract is amended later by the borrower and the lender. We are concerned with the possibility that the fewer observed amendments are driven by shorter loan maturity after CDS trading starts. We mitigate the effect of changes in maturity by scaling the number of loan amendments by the stated maturity in the original loan contract and conduct the same regressions with the scaled variable in column 3. The coefficient is still negative and significant. This suggests that the average number of amendments is reduced by 0.054 (or 39.1% relative to the mean of the sample) each year following loan origination. These results are consistent with CDS lowering lender monitoring via loan contract provisions and thereby making subsequent renegotiations between borrowers and lenders less valuable. Therefore, our finding that loans are amended less often after CDS introduction is consistent with our previous finding on the negative relation between CDS availability and loan contractual protection.

V. Conclusion

This study provides the first empirical evidence on how the trading of credit default swaps (CDS) affects bank monitoring via loan contract terms. We show that, once CDS on a firm begin trading, loans are issued with less restrictive requirements on the firm's collateral and minimum net worth. The effect is stronger when the CDS market is deeper, when the lender takes on larger credit derivatives positions, and when there are fewer debt-equity and within-creditor conflicts. Theories suggest that when the bargaining and renegotiation costs of loan contracts outweigh the costs incurred from agency problems, initial contracts

²³We compare the average number of amendments in our sample with that in the extant literature. Conditional on a renegotiated loan, the average number of amendments over the average stated loan life of 50 months is 5 in our sample. Roberts (2014) reports that each loan experiences 3.5 renegotiations over an average loan life of 51 months.

with less protective terms could be optimal. Indeed, we find that loan contracts are less frequently amended when there are CDS available at the time of loan closing. This evidence is consistent with the view that CDS, as market-based credit protection devices, may substitute for traditional bank monitoring via loan contract terms especially for good quality borrowers.

Our findings further the understanding how credit derivatives trading can affect financial contracting. We show that the availability of CDS can have a substantial impact on ex ante lender commitment to monitoring through non-price loan contract terms. Our findings can provide useful evidence for policy debates, especially given the increasing regulatory actions on CDS (e.g., the implementation of Title VII of the Dodd-Frank Act and the settlement in CDS lawsuit²⁴). Nevertheless, we must emphasize that, although our evidence is consistent with the view that contract loosening by CDS is beneficial to both lenders and borrowers in terms of reducing contracting costs, establishing the overall welfare effect of CDS trading requires further study.

Appendix: Variable Definition

Variable	Definition
<u>CDS Market Characteristics</u>	
CDS Trading	A dummy variable representing whether there are CDS contracts referencing the borrower's debt at the time of loan initiation
CDS Traded	A dummy variable representing whether the borrower ever had a CDS market on its debt at any time during the sample period
CDS Trading Volume /Total Amount of Debt	The number of CDS trades referencing the borrower's debt in the quarter (or month) of loan initiation scaled by total amount of debt in the prior quarter
CDS Outstanding Amount /Total Amount of Debt	The number of outstanding CDS contracts referencing the borrower's debt in the quarter (or month) of loan initiation over the total amount of debt outstanding of the borrower by the end of the prior quarter
<u>Loan Characteristics</u>	
Secured	A dummy taking one if the loan is secured by collateral at issuance and zero otherwise
Net Worth Requirement	$1 - \Phi[(w - \underline{w})/\sigma]$, where Φ is the standard normal cumulative distribution function; w is the logarithm of the value of (tangible) net worth of the borrower at the end of the quarter prior to loan initiation; \underline{w} is the logarithm of the minimum (tangible) net worth that the firm must maintain during the life of the loan required by a net worth covenant; σ is the standard deviation of the quarterly change in the logged value of (tangible) net worth across all loans, varying by the 1-digit SIC industry and year (industry-year volatility) of net worth volatility
Loan Amount (\$Million)	The aggregated amount of facilities that comprise a loan package in \$million
Maturity	The equal-weighted average maturity of the facilities that comprise a loan package
Loan Spread	The equal-weighted average all-in-drawn spread of facilities that compose a loan package
Number of Lenders	The number of banks that participate in the loan syndicate, including both lead banks and participating banks. For sole-lender loans, it equals one
<u>Borrower Characteristics</u>	
<i>*All firm financial information is extracted at the end of the quarter prior to loan issuance</i>	
Total Assets (\$Billion)	The total book assets of the firm
Current Ratio	Total current assets/total current liabilities
Leverage	Total book debt/total book assets
Total Amount of Debt	Short-term debt + 0.5*long-term debt outstanding
Market-to-Book	Market value of equity/book value of equity
Has S&P Rating	A dummy taking one if the borrower has an S&P credit rating available for long-term issuer
Net Worth	Total assets - total liabilities
Tangible Net Worth	Total assets - total liabilities - intangible assets
Profitability	Operating income before depreciation/total assets
Tangibility	Tangible assets/total assets
Altman's Z-score	$3.3 * \text{EBIT}/\text{total assets} + 0.999 * \text{sales}/\text{total assets} + 1.4 * \text{retained earnings}/\text{total assets} + 1.2 * (\text{current assets} - \text{current liabilities})/\text{total assets} + 0.6 * \text{market value of equity}/\text{total liabilities}$
EBITDA Volatility	The standard deviation of quarterly EBITDA
Excess Stock Return	The quarterly stock return less the contemporaneous value-weighted market return, calculated from monthly returns
Stock Return Volatility	The standard deviation of monthly stock returns in a given quarter

Table I
Sample Distribution

This table describes the distribution of sample loans and loans issued to CDS-referenced firms by year. CDS-referenced firms refer to firms that have CDS contracts outstanding that reference the firm's debt in the quarter of loan initiation. A loan (package) is composed of facilities (tranches). Sample loan data are extracted from the Loan Pricing Corporation (LPC)'s Dealscan database. Columns 2 and 6 report the number of loans in the whole sample and loans issued by CDS-referenced firms. Columns 3 and 7 report the number of unique borrowers in each year. Columns 4 and 8 report the proportion of loans secured by collateral out of total loans (or loans to CDS-referenced firms). A loan package is imposed either a total net worth requirement or a tangible net worth requirement, or neither of them. Columns 5 and 9 report the tightness of net worth requirement averaged across loans. Net worth requirement is calculated as: $1 - \Phi[(w - \underline{w})/\sigma]$, where Φ is the standard normal cumulative distribution function; w is the logarithm value of (tangible) net worth of the borrower at the end of the quarter prior to loan initiation; \underline{w} is the logarithm of the minimum (tangible) net worth that the firm must maintain above during the life of the loan, required by the (tangible) net worth covenant; σ is the standard deviation of the quarterly change in the logged value of (tangible) net worth across all loan packages, varying by the 1-digit SIC industry and by year. A larger requirement measure represents a stricter requirement on the firm's (tangible) net worth.

Year	All Sample				Loans to CDS-Referenced Firms			
	# of Loans	# of Unique Firms	Ratio of Secured Loans	Net Worth Requirement	# of Loans	# of Unique Firms	Ratio of Secured Loans	Net Worth Requirement

Table II
Summary Statistics of Sample Loans and Borrowers

This table reports the summary statistics of our sample loans and borrowing firms. Loan amount refers to the amount of loan at package level in \$million. *Loan Spread* is the all-in-drawn spreads in basis points. It is averaged across facilities that comprise one loan package. *Maturity* refers to the average maturity of facilities of each loan package in months. *Number of Lenders* refers to the number of lead banks and participating banks in a loan syndicate. For sole-lender loans, the number of lenders equals one. *Secured* is a dummy taking one if the loan is secured by collateral. *Net Worth Requirement* is constructed following the method introduced in Table I. All loan characteristics are extracted from the initial loan contract. Borrower characteristic variables are extracted at the end of the quarter prior to loan initiation and summarized in the lower rows. *Leverage* refers to the book leverage, calculated as (short-term debt+0.5*long-term debt)/total assets. *Profitability* is the ratio of quarterly operating income before depreciation to total assets. *Current Ratio* is the ratio of current assets over current liabilities. *Tangibility* is the ratio of tangible assets relative to total assets. *Market-to-Book* is the ratio of market value of equity to book value of equity. *Has S&P Rating* is a dummy taking one if the borrower has a S&P long-term credit rating available at loan initiation. *Altman's Z-score* is calculated as $3.3 * \text{EBIT} / \text{total assets} + 0.999 * \text{sales} / \text{total assets} + 1.4 * \text{retained earnings} / \text{total assets} + 1.2 * (\text{current assets} - \text{current liabilities}) / \text{total assets} + 0.6 * \text{market value of equity} / \text{total liabilities}$.

Table III
Impact of Borrower CDS on Loan Contractual Protection

This table reports the baseline difference-in-differences regression results of the effects of CDS trading in borrower's name on loan contractual protection devices. The dependent variables are the secured dummy and the net worth requirement. The independent variable we are interested in is *CDS Trading*, a dummy variable which takes the value of one if CDS are actively traded in the borrower's debt when the loan is initiated, and zero otherwise. *CDS Traded* is a dummy variable which takes the value of one if the borrower ever had a CDS market at any point of time during the sample period, and zero otherwise. Borrower characteristic variables are extracted at the end of the quarter prior to loan initiation. All specifications control for loan purpose, loan origination year and borrower 1-digit SIC industry fixed effects. Dealscan reports 6 types of loan purposes: corporate purposes, debt repayment, working capital, takeover, CP backup and others. Numbers in parentheses are standard errors adjusted for heteroskedasticity and clustered at firm-level. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IV
CDS Endogeneity Control: Instrumental Variable (IV) Approach

This table reports the two-stage-least-square regression results of the impact of CDS trading on loan contractual protection. In the first stage we estimate an OLS model to obtain the fitted value of the independent variable, *CDS Trading*, using the instrumental variable *Past Lender's Foreign Exchange Derivatives Position*. *Past Lender's Foreign Exchange Derivatives Position* is the amount of foreign exchange derivatives used for hedging purposes (not trading) relative to the amount of loans of the lead syndicate banks that the firm has borrowed money from in the past five years. In the first-stage regression, the dependent variable is *CDS Trading*, a dummy variable which takes the value of one if CDS trading referencing the borrower's debt is active at loan origination, and zero otherwise. The explanatory variables include the one quarter lag of the following: the logarithm of total assets, leverage, cash-to-total assets, tangibility, profitability, current ratio, market-to-book ratio, Altman's Z-score, the logarithm of fixed charge coverage, excess stock return, and the logarithm of stock market volatility. The dependent variables in the second stage are the secured value of CDS and the tightness of net worth requirement. The independent variable of interest is the fitted value of CDS trading estimated from the instrumental variable. We use the same control variables as we use in the baseline regressions. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. First-stage regression results are reported by Internet Appendix Table IA2. See Appendix for variable definitions.

Variable	Secured Loan	Net Worth Requirement
	Model1	Model2
Fitted Value of CDS Trading	-0.068*** (0.008)	-0.069** (0.035)
Log (Loan Spread)	0.158*** (0.005)	0.016*** (0.002)

Observations	23612	4829

Table V
CDS Endogeneity Control: Propensity Score Matching

This table reports the results of regressions that examine the impact of CDS trading on loan contractual devices using a matched sample of loans, which is formed by matching on the propensity scores of CDS trading. We estimate a probit model to obtain the propensity scores of CDS trading for each loan observation. In the first stage, the explanatory variables include the one quarter lag of the following: the instrumental variable (*Past Lender's Foreign Exchange Derivatives Position*), the logarithm of total assets, leverage, cash-to-total assets, profitability, current ratio, and Altman's Z-score. After the propensity scores are obtained, we employ the nearest neighborhood matching to form the control group. We select the one from the same 1-digit SIC industry non-CDS firms that has the nearest propensity score to the CDS firm as the matching firm. Then we extract the loans issued by the matching firm in the same year as the CDS firm to form the matching group of loans. The independent variable we are interested in is *CDS Trading*, a dummy variable which takes the value of one if there is CDS contracts referencing the borrower's debt at loan initiation, and zero otherwise. *CDS Traded* is a dummy taking one if the borrower has a CDS market at any point of time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table VI
Impact of Borrower CDS Market Liquidity

This table reports the regression results of the effects of CDS market liquidity on loan contractual protection terms. The dependent variables are the secured dummy and the net worth requirement specified in the initial loan contract. The independent variables of interest are (1) the number of outstanding CDS contracts referencing the borrower's debt in the quarter of loan initiation scaled by the amount of total outstanding debt in the prior quarter (*CDS Outstanding Amount/Total Amount of Debt*); (2) the number of CDS trades referencing the borrower's debt in the quarter of loan initiation scaled by the amount of total outstanding debt in the prior quarter (*CDS Trading Volume/Total Amount of Debt*). In all specifications, we control for CDS firm fixed effect, *CDS Traded*, a dummy variable taking one if the borrower has a CDS market on its debt at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions in Table III. To conserve space we do not report coefficients of all control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table VII
Lender Credit Derivatives Position and the Impact of Borrower CDS

This table reports the regression results of the impact of lenders' credit derivatives positions on the CDS effects. The dependent variables are the secured dummy and the net worth requirement specified in the initial loan contract. The independent variables we are interested in are the interaction terms of *CDS trading* and syndicate *Lead Lenders' Credit Derivatives Position* (in \$trillion). Lead lenders' credit derivatives positions are extracted in the quarter of loan initiation. Banks' credit derivatives trading data are provided by the Federal Reserve Consolidated Financial Statements for Bank Holding Companies ("FR Y-9C") and the Office of the Comptroller of the Currency (OCC) Quarterly Report on Bank Derivatives Activities. *CDS Trading* is a dummy variable which takes the value of one if there is active CDS trading in the borrower's debt at loan initiation, and zero otherwise. *CDS Traded* is a dummy variable taking one if the borrower has a CDS market at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. To conserve space we do not report all coefficients of control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table VIII
Borrower Credit Quality and the Impact of Borrower CDS

This table reports the regression results that examine the impact of borrower credit quality on the CDS effects. The dependent variables are the secured dummy and the net worth requirement specified in the initial loan contract. The independent variable we are interested in is the interaction term of *CDS Trading* and *Higher Altman's Z-score*, a dummy representing whether the borrowing firm has higher Altman's Z-score, which is determined by the 50% breakpoints across all sample firms at the end of the quarter prior to loan initiation. *CDS Trading* is a dummy taking one if there is an active CDS market referencing the borrower's debt at loan origination, and zero otherwise. *CDS Traded* is a dummy taking the value of one if the borrower has a CDS market on its debt at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. To conserve space we do not report all coefficients of control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IX

Lead Lender-Participant Lender Past Collaboration and Impact of Borrower CDS

This table reports the regression results that examine how the lead lender and participant lenders' past collaboration affects the impact of borrower CDS. We measure the past collaboration using a dummy *Lead Lender-Participant Lender Past Collaboration*, which takes one if the lead bank and any of the participant banks acted as syndicate lenders in the same syndicate loan in the past five years. *CDS Trading* is a dummy taking the value of one if there is active CDS trading referencing the borrower's debt at loan origination, and zero otherwise. *CDS Traded* is a dummy taking one if the borrower ever has a CDS market on its debt at any time during the sample period, and zero otherwise. We use the same control variables as we use in the baseline regressions. To conserve space we do not report the coefficients of all control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. All results are based on quarterly observations. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table X
Impact of Borrower CDS on Loan Outcome: Loan Contract Amendment

This table reports results of regressions that examine the impact of the borrower CDS on loan amendment after initiation. The dependent variables are measures for the frequency of loan amendments. In model 1, the dependent variable is a dummy *Ever Amended* which takes one if the loan is amended at least once after initiation. In model 2, the dependent variable is the *# Amendments*, which is the total number of amendments made to the loan after initiation. In model 3, the dependent variable is the average number of amendments per year throughout the life of the loan. The independent variable of interest is *CDS Trading*, a dummy variable taking one if there is active CDS trading referencing the borrower's debt at loan origination, and zero otherwise. *CDS Traded* is a dummy variable if the borrower has CDS market at any time during the sample period, and zero otherwise. We control for loan contract terms in the initial contract and borrower characteristics which are extracted at the end of the quarter prior to loan initiation. We also control for Δ firm characteristics including firm size, profitability, leverage and volatility between the quarter before loan initiation and the current quarter (of loan amendment). EBITDA volatility is the standard deviation of quarterly EBITDA measured on yearly basis. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Internet Appendix to

“Do Banks Still Monitor When There is a Market for Credit Protection?”

Table IA.1

Impact of Borrower CDS: Restricted Sample of Loans by Skipping Short Windows

This table shows the regression results of the effects of CDS trading on loan contractual protection measures with a restricted sample of loans. We exclude loans issued within short windows immediately after CDS introduction to alleviate endogeneity concern. Specifically, we exclude loans issued within one year after first CDS introduction in models 1 and 2, loans issued within two years in models 3 and 4, and loans issued within three years in models 5 and 6. We are interested in the coefficients of *CDS Trading*, a dummy variable taking the value of one if there are CDS contracts referencing the borrower's debt at loan origination, and zero otherwise. *CDS Traded* is a dummy variable if the borrower has CDS market at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IA.2
First-Stage Regressions of the Instrumental Variable Approach

This table shows the first-stage OLS regression of CDS trading on the instrumental variable. The sample is composed of loans in Dealscan with the instrumental variable and financial information available. The dependent variable is *CDS Trading*, a dummy taking one if there are CDS contracts referencing the borrower's debt in the quarter of loan initiation. The instrumental variable is *Past Lender's Foreign Exchange Derivatives Position*, which is the amount of foreign exchange derivatives used for hedging purposes (not trading) relative to the total amount of loans of the syndicate lead banks that the firm has borrowed money from in the past five years. Data on banks' foreign exchange derivatives position are from the Federal Reserve's Call Report on commercial banks and bank holding companies. Other explanatory variables are extracted at the end of the quarter prior to loan origination. Excess stock return and stock return volatility are calculated from monthly stock returns. The first-stage regression includes year and industry fixed effects. We form the sample by keeping loans for CDS-referenced firms originated from 1994 until the first quarter when CDS trading started, and all loans issued by the non-CDS borrowers. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Variable	Estimate

Table IA.3**Matched Sample Diagnostics: Nearest Neighbor Matching on Propensity Scores**

This table compares differences in propensity scores and borrower characteristics between CDS firms and Non-CDS firms for the original sample and the nearest neighbor matched sample. The matching is based on the propensity of CDS trading estimated from a probit model, in which the dependent variable is *CDS Trading*, a dummy taking one if there are CDS contracts referencing the borrower's debt in the quarter of loan initiation, and the explanatory variables include the instrument, the logarithm of total assets, current ratio, return-on-assets, leverage ratio, and Altman's Z-score. Then we select the one from non-CDS firms in the same 1-digit SIC industry with the nearest propensity score to the CDS firm as the matching firm. We extract loans issued by the matching firms in the same year as the matched CDS firms to form to control group of loans. CDS firms refer to firms that ever have a CDS market referencing its debt at any time during the sample period. Non-CDS firms refer to firms that never have a CDS market during the sample period. Borrower characteristic variables take the value at the end of the quarter prior to loan initiation. The numbers in the first column are the mean of the differences in the corresponding variables between CDS and non-CDS firms before matching. The numbers in the second column are the mean of the differences in the corresponding variables between CDS firms and their one-on-one matched firms. ***, **, and * represent significance level of 1%, 5% and 10% level, respectively, at which the differences are statistically different from zero. See Appendix for variable definitions.

Variable	Before Matching (CDS Firm - Non-CDS Firm)	After Matching (CDS Firm - Non-CDS Firm)
Propensity Score	0.211**	-0.007
Log (Total Assets)	2.536***	-0.054
Current Ratio	-0.537***	0.004
Cash-to-Total Assets	-0.018***	0.003
Leverage	0.016***	-0.005
Profitability	0.008***	0.000

Table IA.4

Impact of Borrower CDS: Other Restrictions on Borrower Risk-Shifting Incentives

This table shows the results of regressions that examine the effects of CDS trading on other types of restrictions on borrower risk-shifting activities. The dependent variables are the tightness measures of the restrictive covenants, which are calculated in the same approach as we use for calculating the net worth requirement. We are primarily interested in three types of restrictions: debt-to-EBITDA ratio, debt-to-tangible net worth, and the leverage ratio. We are interested in the coefficients of *CDS Trading*, a dummy variable taking the value of one if there are CDS contracts referencing the borrower's debt at loan origination, and zero otherwise. *CDS Traded* is a dummy variable if the borrower has CDS market at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. We do not report all coefficients to conserve space. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IA.5
Control Lender Effects: Within-Bank Analysis

This table reports the baseline difference-in-differences regression results of the impact of CDS trading on loan contractual protection devices. Panel A restricts the sample to loans from banks that lend to both CDS and non-CDS firms during the sample period. Panel B further restricts the sample to loans from banks that lend to CDS firms both before and after CDS introduction. The dependent variables are the secured dummy and the tightness of net worth requirement. The independent variable we are interested in is *CDS Trading*, a dummy taking the value of one if there are CDS contracts referencing the borrower's debt when the loan is initiated, and zero otherwise. *CDS Traded* is a dummy variable which takes the value of one if the borrower has a CDS market at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. All specifications include loan purpose, loan origination year and borrower industry fixed effects. All results are based on quarterly observations. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IA.6

Impact of Borrower CDS Market Liquidity: Alternative Measure

This table reports the regression results of the effects of CDS market liquidity on loan contractual protection terms with alternative measures of CDS market liquidity. The dependent variables are the secured dummy and the net worth requirement specified in the initial loan contract. The independent variables of interest are (1) the number of outstanding CDS contracts referencing the borrower's debt in the *month* of loan initiation scaled by the amount of total outstanding debt in the prior quarter (*CDS Outstanding Amount/Total Amount of Debt*); (2) the number of CDS trades referencing the borrower's debt in the *month* of loan initiation scaled by the amount of total outstanding debt in the prior quarter (*CDS Trading Volume/Total Amount of Debt*). In all specifications, we control for CDS firm fixed effect, *CDS Traded*, a dummy variable taking one if the borrower has a CDS market on its debt at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions in Table III. To conserve space we do not report coefficients of all control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Table IA.7
Lenders' Credit Derivatives Position and the Impact of Borrower CDS:
Alternative Measures

This table reports the regression results of the impact of lenders' credit derivatives positions on the CDS effects. The dependent variables are the secured dummy and the net worth requirement specified in the initial loan contract. The independent variables we are interested in are the interaction terms of *CDS Trading* and *All Lenders' Credit Derivatives Position* (in \$trillion), including the positions held by both the lead and participant lenders. Syndicate lenders' credit derivatives positions are extracted at the quarter of loan initiation. Banks' credit derivatives trading data are provided by the Federal Reserve Consolidated Financial Statements for Bank Holding Companies ("FR Y-9C") and the Office of the Comptroller of the Currency (OCC) Quarterly Report on Bank Derivatives Activities. *CDS Trading* is a dummy variable which takes the value of one if there is active CDS trading in the borrower's debt at loan initiation, and zero otherwise. *CDS Traded* is a dummy variable taking one if the borrower has a CDS market at any time during the sample period, and zero otherwise. Other control variables are the same as we use in the baseline regressions. To conserve space we do not report all coefficients of control variables. All specifications include loan purpose, loan origination year and borrower industry fixed effects. Numbers in parentheses are standard errors adjusted for heteroskedasticity and firm-level clustering. ***, **, and * represent statistical significance at 1%, 5% and 10% level, respectively. See Appendix for variable definitions.

Variable	Secured Loan		Net Worth Requirement	
	Model1	Model2	Model3	Model4
CDS Trading*All Lenders' Credit Derivatives Position	-0.021*** (0.006)	-0.020*** (0.006)	-0.028** (0.013)	-0.028** (0.013)
All Lenders' Credit Derivatives Position	-0.008* (0.005)	-0.009* (0.005)	0.004*** (0.001)	0.005*** (0.001)
